ABSTRACT: This paper outlines the development of the NSWS (Nippon Screw Weight System) testing machine, which complies with the Swedish sounding (SWS) test to determine loading and rotational penetration resistance, and which was developed as an in-situ ground surveying device to detect super soft zones in the ground, including hollows and loosening, in detail by allowing operation in the 0 to 2500N load range, with very close measuring interval and penetration speed control, which features cannot be achieved by the SWS testing machine. Additionally, findings from an in-situ surveying of in-ground hollows identified using the NSWS testing machine are reported in this paper. The machine achieved a conversion N-value measuring interval of 2.5cm (or 3.8cm), determination of ranges of hollow and loosening zones through pre-setting of penetration speed, and detection of super soft zones of conversion N-values 1 and below with a load range of 0 to 1000N.

Keywords: NSWS testing machine, in-ground hollow, in-ground loosening zone, conversion N-values

1. INTRODUCTION

With lots of postwar grooming, social capital that supports the development of the country and ensures the safety of its citizens has entered the 21 century. Most of the constructions are about to pass 50 years now. Meanwhile, related technology is also moving from construction to maintenance, and it is now important to utilize the limited resources effectively; at the same time, “restoration” and “assessment” of social capital has become important for continuing its fundamental functionalities.

For example, although there are some direct factors such as ocean waves, flooding, etc. that cause the destruction of coastal revetment walls, one reason behind the destruction of only a particular zone of the continuing shore can be the presence of hollows and loosening zones in the back side zone of the shore ground. Generally, hollows and loosening zones develop invisibly in the ground over time due to continuous ocean waves or the flowing waters of the ocean or river, and also due to sediment discharge caused by high tidal waves, abnormal flooding, or the presence of underground water. If development of hollows and loosening zones in the ground is considered a disintegrative process for the in-ground structure such as a sea bank, sea shore, roads, etc., then an in-ground testing machine to investigate and evaluate that process is absolutely necessary as a technology for “restoration” of the in-ground structures. Further, a ground surveying technology that targets “restoration” of

in-ground structures strongly demands an efficient or economically efficient in-situ testing method with promptness of result or continuity of data and which can evaluate the conditions of the ground more accurately [1], [2].

The Swedish sounding (SWS) test is an in-situ ground surveying method that determines penetration resistance value (N_{sw}) by rotations with the lowest load (W_{sw}) required for penetration and the 1000N static load [3]. Basically, it is developed for investigating the bearing capacity of roadbeds. However, it has been used in many instances of coastline surveying; since there are fewer constraints about the ground in static sounding, measurements upto 15m are possible, and the testing machine can also be disassembled to a portable size. However, the measurement interval in the SWS test is a high 25cm.

Here, while considering the bank water leakage, which is one of the reasons for flooding, it is necessary to identify the leakage points and their size and locations and to grasp the status of sediment discharge of the ground. For that, it is necessary to define boundaries for 3 different geological strata i.e. of gas, liquid and solid phases; at the same time it is required to identify super soft zones in the ground including hollows and loosening, and these should be measured at intervals of 5cm or less; also, an indicator for determining their condition is necessary. This brings into the picture (see Fig. 1) the development of the NSWS (Nippon Screw Weight System) testing machine, which complies with the SWS test and which was developed as an in-situ ground surveying device to detect super soft zones in the ground including hollows and loosening in detail by hydraulic and pneumatic control of loading and with very closely spaced measurement capability [4]-[6].

This paper outlines the development of the NSWS testing machine (see Fig. 1), which complies with the conventional SWS test to determine loading and rotational penetration resistance, and which was developed as an in-situ ground surveying device to detect in detail super soft zones in the ground including hollows and loosening by allowing operation in the 0 to 2500N load range, very frequent measuring interval and penetration speed control, which features cannot be achieved by the SWS testing machine. Findings from an in-situ surveying of in-ground hollows using the NSWS testing machine are reported in this paper.

2. OVERVIEW OF NSWS TESTING MACHINE

2.1 Development and Characteristics of NSWS Testing Machine

Even though the SWS testing machine is easily portable, testing time is short, the testing methods are simple and the cost of testing is affordable compared to mechanical boring, these testing methods cannot be applied on dense sandy ground layer, gravel, or rocky ground layer [6]. Also, the measuring intervals in the conventional standard penetration test or SWS test are too large to identify the different soil structures, stratum barriers or locations of bleeding channels, existence of hollow ground and loosening in the surrounding soil, etc. Measurements should ideally be possible at intervals of 5cm or less.

Therefore, an in-situ ground surveying device i.e. the NSWS testing machine has been developed that can identify super soft zones in the ground; it provides hydraulic and pneumatic control of loading as well as closely spaced measuring intervals using the measurement system with the loading and rotational penetration resistance of the SWS testing machine [4]-[6]. There are two types of NSWS testing machines: the model 1200 (maximum load 1200N and measuring intervals of 2.5cm) which has been developed for super soft zones, and the model 2500 (maximum load 2500N and measuring intervals of 3.8cm) that enables penetration in gravelly or rocky ground layers.

The NSWS testing machine has the following characteristics:

- (1) Lightweight and compact (total weight 70 to 75kg, total length × total width × total height = 70 to 75 × 50 × 250cm); easily portable.
- (2) Can control the load continuously from 0 to 1200N or from 0 to 2500N by using the load method with hydraulic and pneumatic controls.

- (3) Resolution of super soft zones can be increased significantly according to the load from zero.
- (4) Internal structure of the ground can be understood in detail almost continuously by measuring the load, penetration depth and the number of rotations with 2.5cm or 3.8cm intervals.
- (5) Can measure penetration time while loading, and can detect ground self-subsidence (hollow and loosening) zone in the ground from the penetration speed.
- (6) Can measure the direction of tilt on the surface and the slope on the ground.
- (7) Can identify in-situ the hollow or loosening zone.

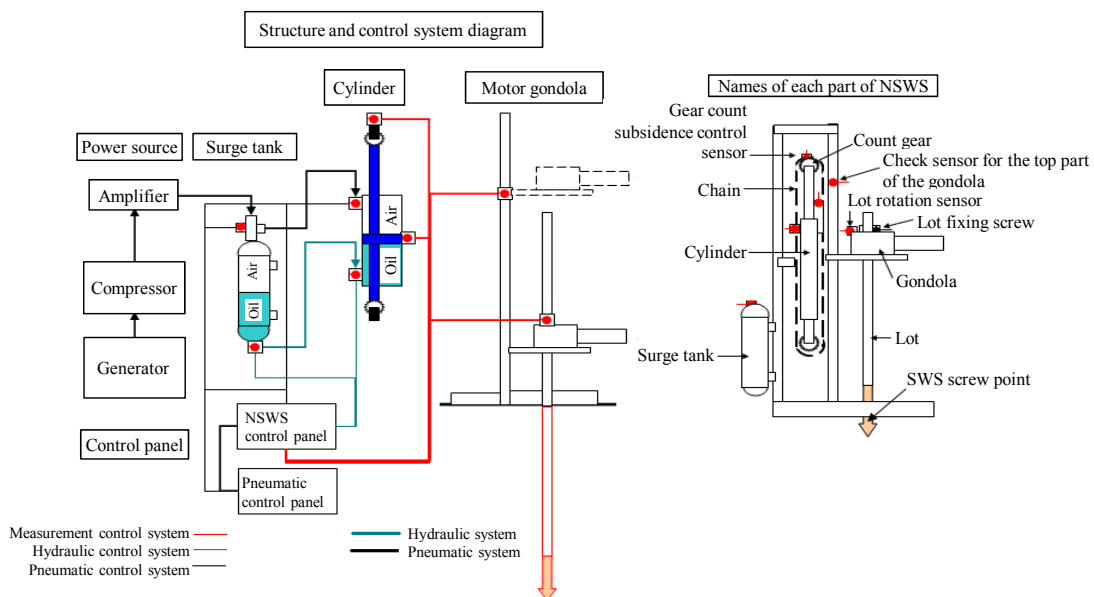

Figure 2. NSWS structure and applied load condition

2.2 Functionalities of NSW Testing Machine

(1) Amount of load

Regarding the loading machine of the SWS test, even though an automatic testing machine has been developed and is widely used because of its efficiency, it has some limitations, one of which is that the total self-weight of the motor which is a rotational device and the loading gondola is approximately 500N, which makes the measurement of zones with initial loading of less than 500N not possible. Therefore, measurements from zero are not possible.

As shown in Fig. 2, for the self-weight of motor + gondola, the 2 cylinders for hydraulic and pneumatic actions, load is applied in the opposite direction to produce zero load condition, and successive load measurement from 0 to 2500N is made possible in the SWS testing machine. Further, accuracy of the load is maintained by carrying out calibration using a calibration measuring device.

(2) Measuring intervals

The gondola in the NSW testing machine is structured as a moving pulley using gears that are fixed in the cylinder and chains that are suspended. A chain feed length of twice of the moving distance of the cylinder (chain pitch = gear pitch, $1.25 \times 2 = 2.5\text{cm}$ or $1.9 \times 2 = 3.8\text{cm}$) is sensed through a sensor, and this length is used as a measuring unit. In contrast to the conventional SWS test with measurement interval of 25cm, detailed data can be acquired using the NSW testing machine. Also, by using the measurement control time for very closely spaced measuring intervals, the time required for penetration can be defined beforehand and detection of scuttle conditions or super soft zones like hollow and loosening zones can be possible.

(3) Slope measurement

Since the load control of the NSW testing machine is a hydraulic and pneumatic control system, it can be loaded irrespective of the direction of load action, thereby making the measurement of slope possible (see Fig. 3). Due to this, as shown in Fig. 4, the range of the hollow or extremely loose soil (loosening zone) can be determined.

(4) Identifying in-ground hollows and loosening zones

The NSW testing machine controls the rotations and the load strictly with penetration time in the measuring interval as a parameter and identifies the hollow and loosening zones. An example of a measurement result of the NSW testing machine, along with explanation, is provided in Fig. 5. There, the time for measurement data transfer and the penetration time required for the measuring unit interval (2.5cm) are processed through a computer. If the value is more than or equal to the preset penetration time (settlement time) of 0.5 second (variable), rotation or loading is stopped and the measurements are re-started by returning the load to zero. The in-ground hollow and loosening zones are then identified by comparing actual load status with the detection accuracy in case of less than or equal to the “set penetration time” or “continuation of that time”. A total of 4 abnormal zones with depth 0.75 to 1.5m are detected as seen in Fig. 5; it can therefore be inferred that there are hollow and

Figure 3. Appearance of slope measurement with NSW testing machine

Figure 4. Concept of detection for hollow or loosening zone in ground

loosening zones within that area.

Since a hollow rod is used in the NSW testing machine while identifying the in-ground hollow and loosening zones, it can be fitted with devices like a camera or a water gauge to allow visualization of those in-ground hollows or to figure out the existence of water etc. in the hollows. Additionally, pressure relief control type high-viscosity pumps are used incrementally in the NSW testing machines. Identified in-ground hollows and loosening can be repaired simply by injecting cement, water-swelling material, etc. [5].

3. IN-GROUND HOLLOW SURVEYING USING NSWS TESTING MACHINE

3.1 Overview of Ground Surveying Site

Before restoring water flow in the sewer pipe, in-ground hollow around the particular sewer pipe approximately 6.5m below the ground surface was investigated using the NSWS testing machine (model 1200; maximum amount of load 1200N; measuring interval 2.5cm).

There are two methods for investigating the soil condition of the area where hollows etc. are expected to develop under the ground surface. The first is a direct method, like test drill investigation, boring (Standard penetration testing), and SWS testing; the other is an indirect method such as underground radar exploration and elastic wave tomography exploration. The hollow expected under that site is above the sewer pipe ($\phi 1000\text{mm}$) and spread deep around the 6m. Further, geological conditions at the site can be identified (see Fig. 6) from the existing boring test result. The result shows that the groundwater level is high and there is loose sandy soil and extremely soft cohesive soil with N-value = 0 to 6. That makes it difficult to detect the in-ground hollows even after geological explorations like underground radar exploration, high density surface wave exploration, shallow seismic reflections and high density electric wave exploration. Also, it is difficult to grasp the minute soil conditions of soft ground even after pilot boring.

3.2 Steps for In-Situ Ground Surveying

Following are the steps for in-situ ground surveying aiming to identify the soil conditions of the upper side of the sewer pipe in the water flow (see Fig. 7).

- (1) In-ground hollow surveying should be carried out after removing the sewer pipe in the water flow ($\phi 350\text{mm}$).
- (2) Adjust the sequential direction and the angle of every test hole (1) to (3), execute the test in the direction towards the top surface and horizontal direction of the sewer pipe in the water flow line and identify the soil condition focusing on the top surface of damaged places of the sewer pipe in the water flow (see Fig. 7).
- (3) Based on the result of test holes (1) to (3), perform testing at further test holes (4) to (6) and identify the soil condition from the vertical and horizontal directions of the top surface (see Fig. 7).

3.3 Details of Test Holes

Upper elevation of the sewer pipe in the water flow under the site is approximately $H = -6.0\text{m}$, and depth of each test hole is below this elevation. Table 1 shows the details of each test hole.

As test hole 1), tested the position 45° downward in normal direction (northerly direction) from the position close to the pillar position. Hole length is 7.4m and test depth is 5.2m ($H = -6.0\text{m}$).

As test hole 2), tested the position 45° downward from a position close to the pillar position, about 45° to the south from sewer pipe direction. Hole length is 8.2m and test depth

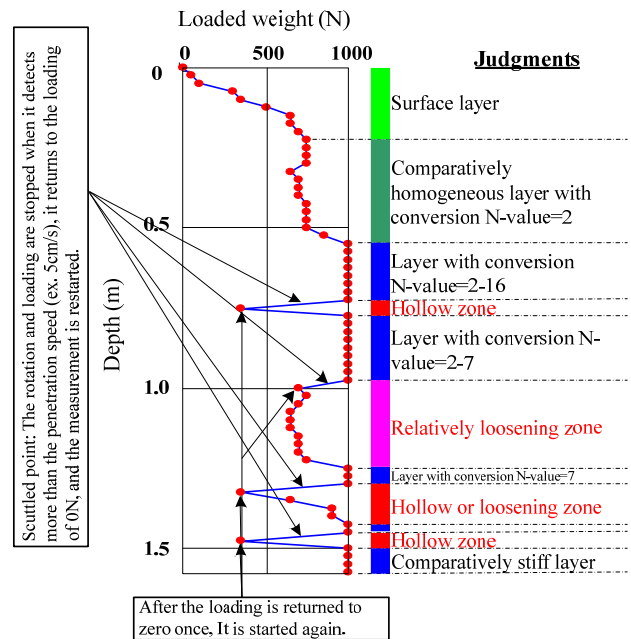

Figure 5. An example of result and interpretation on measurement with NSWS testing machine

Figure 6. Geological conditions at vicinity of investigation ground measured by existing boring test

is 5.8m ($H = -6.6\text{m}$)

As test hole 3), tested the position 45° downward from a position close to the pillar position, about 135° to the south from sewer pipe direction. Hole length is 8.07m and test

depth is 5.7m (H=-6.5m).

Using test holes 1) to 3), tested a fan-like shape of 135° at the south in normal direction from the sewer pipe. Additionally, after finishing test holes 1) to 3), Fig. 8 shows that the entire soil near the border of the embankment around the pillar position and cohesive soil is soft; however, even though the soil conditions are almost similar to the existing pilot boring result (see Fig. 6), no results could be obtained indicating any significant hollow. Therefore, testing of places far from the pillar position is carried out in the vertical direction as test holes 4) to 5) in order to determine whether the soil condition there is soft similar to test holes 1) to 3).

In test holes 1) to 5), it was found that the soil condition was entirely soft, but since there was no indication of a significant hollow, it was assumed that the extent of hollow is not much and therefore tested one place immediately near the pillar position as test hole 6).

3.4 Test Result (Conversion N-value)

Using the Inada method [7], a test result is obtained from the number of half rotations (N_{sw}) and amount of load (W_{sw}), and the result is taken as a conversion N-value in every depth and the result of every test position is shown in Figs. 9, 10, 11, 12, 13 and 14. Here, from the report in the Okita et al. (2010), it is clear that the NSWS test and SWS test for conversion N-value by the Inada method indicated in Tamura et al. (2004) have high correlation.

In test hole 1), except for the embankment, depth curve of conversion N-value increased gradually from 2.5 to 5.0 and no decline was observed in the middle. Therefore, no hollows or loosening were found in test hole 1) (see Fig. 9). In test hole 2), except for the embankment, depth curve of conversion N-value changed gradually from 2.0 to 5.0 and even though there were some abnormal values in between due to the presence of stones, no major declines were observed. Therefore, no hollows or loosening were found in test hole 2) (see Fig. 10).

In test hole 3), except for the embankment, depth curve of conversion N-value changed gradually from 2.0 to 5.0 and even though there were some abnormal values in between due to the presence of stones, no major declines were observed. Therefore, no hollows or loosening were found in test hole 3) (see Fig. 11).

In test hole 4), except for the embankment, depth curve of conversion N-value changed gradually from 2.5 to 5.0 and even though there were some abnormal values in between due to the presence of stones, no major declines were observed. Therefore, no hollows or loosening because of existence of hollows were found in test hole 4) (see Fig. 12). In test hole 5), except for the embankment, depth curve of conversion N-value changed gradually from 2.5 to 5.0 and even though there were some abnormal values in between due to the presence of stones, no major declines or changes were observed. No hollows or loosening were found in test hole 5) including the embankment (see Fig. 13).

Test hole 6) is a test executed 0.5m away from the pillar

Figure 7. Outline of implementation plan for in-situ ground surveying with NSWS testing machine

Table 1. Details of each test hole

Test hole	Ground elevation (m)	Inclined angle (degrees)	Extension (m)	Altitude in test point (m)
1)	-0.75	45	7.40	-5.98
2)	-0.75	45	8.20	-6.55
3)	-0.75	45	8.07	-6.46
4)	-0.48	90	4.98	-5.46
5)	-0.42	90	5.98	-6.40
6)	-0.93	90	5.23	-6.16
Total			39.86	

Altitude in upper end of the sewer pipe: H=-6.0m

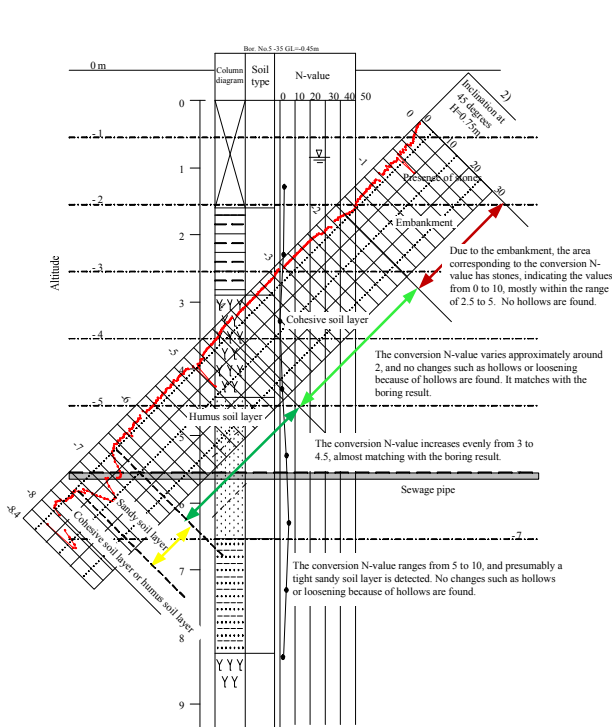

Figure 10. Distribution of conversion N-value toward depth directions in test hole 2)

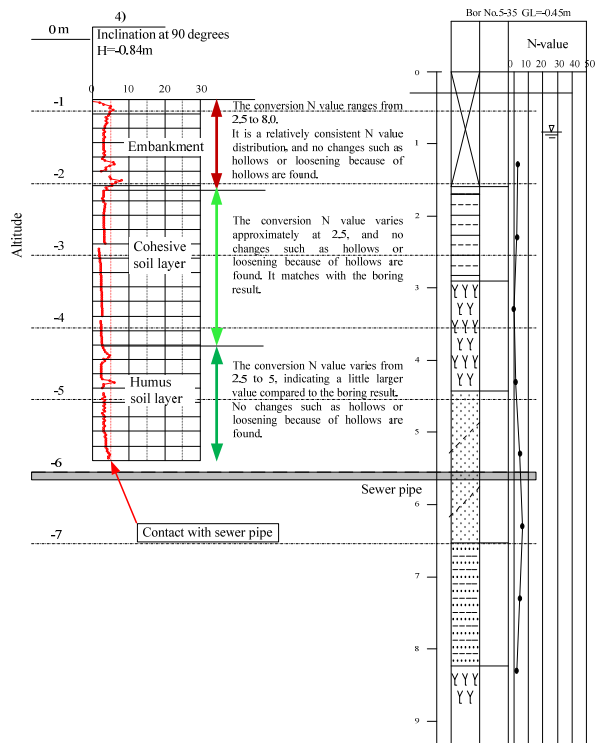

Figure 12. Distribution of conversion N-value toward depth directions in test hole 4)

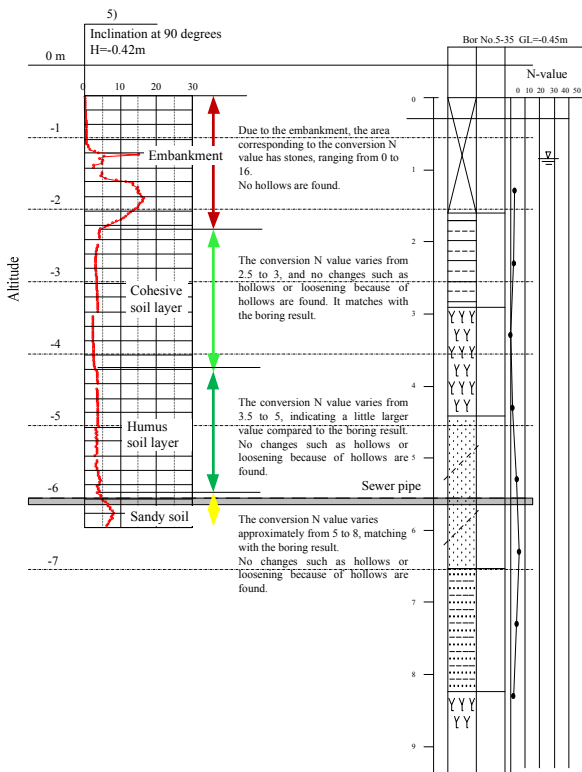

Figure 13. Distribution of conversion N-value toward depth directions in test hole 5)

Figure 14. Distribution of conversion N-value toward depth directions in test hole 6)

position in a vertical direction. Depth curve of conversion N-value, except for the embankment, is uniformly 2.5 to 3.0 up to around -4m near elevation; compared with the former test holes 1) to 5) at depth of -4m or more, it is 2.5 or less; also, some changes different from test holes 1) to 5) can be found, such as decrease near -4.5m elevation. Also, 20cm immediately above the sewer pipe, conversion N-value suddenly changes from 2.5 to 1, which indicates that there is a hollow in this area. Therefore, in test hole 6) which is 0.5m away from the pillar position, loosening is caused from the first top 2m of the sewer pipe, which indicates a hollow near the sewer pipe (see Fig. 14).

3.5 Determining an In-Ground Hollow

Fig. 15 indicates the geological longitudinal diagram projecting a result of test holes 1) to 6) onto the center line of a sewer pipe. In test hole 1), extremely soft zones having conversion N-value less than or equal to 2 at the embankment were identified. To determine whether this soft layer had formed due to damage to the sewer pipe, extensive testing was executed focusing on the pillar position. At the site, a range of loose soil types are spread from previous test boring adjacent to the sewer pipe and, therefore, there are chances of hollows spread under the paved surface (see Fig. 6). According to the test result of the area immediately above the damaged places (test holes 1) to 3)) and the surrounding test holes 4) to 5), no super soft zones indicating presence of hollows were detected, and it can be concluded that the area to 6m deep from the pipe is uniformly of very soft sandy soil and humus soil with conversion N-value from 2.5 to 5, excluding the embankment. On the other hand, in the area near the pillar position (test hole 6)), hollows were detected 20cm immediately above the sewer pipe and, unlike with test holes 1) to 5), the area up to 2m above the pipe is extremely soft with conversion N-value less than or equal to 2. The range of hollows and loosening in the testing phase is within 2m above damaged places (see Fig. 16) and not under the paved surface.

4 CONCLUSIONS

The NSWS testing machine can provide detailed soil information that was previously difficult to gain through conventional in-situ ground surveying methods. It can be an effective surveying tool to establish restoration or disaster prevention techniques for in-ground structures, investigating the current problems of hollows under river banks, tanks, buried valley embankments, widening of embankments, the seacoast and river structures, investigating road damage caused by underground objects like sewer pipes, etc. Also, in this paper, in-situ surveying of in-ground hollows around a sewer pipe was performed using the NSWS test machine. As a result, hollows and loosening in the ground were identified. Also, the machine allows closely spaced measuring intervals of 2.5cm (or 3.8cm), determination of ranges of hollow and loosening zones through pre-setting of penetration speed, and detection of super soft zones of N-values 1 and below

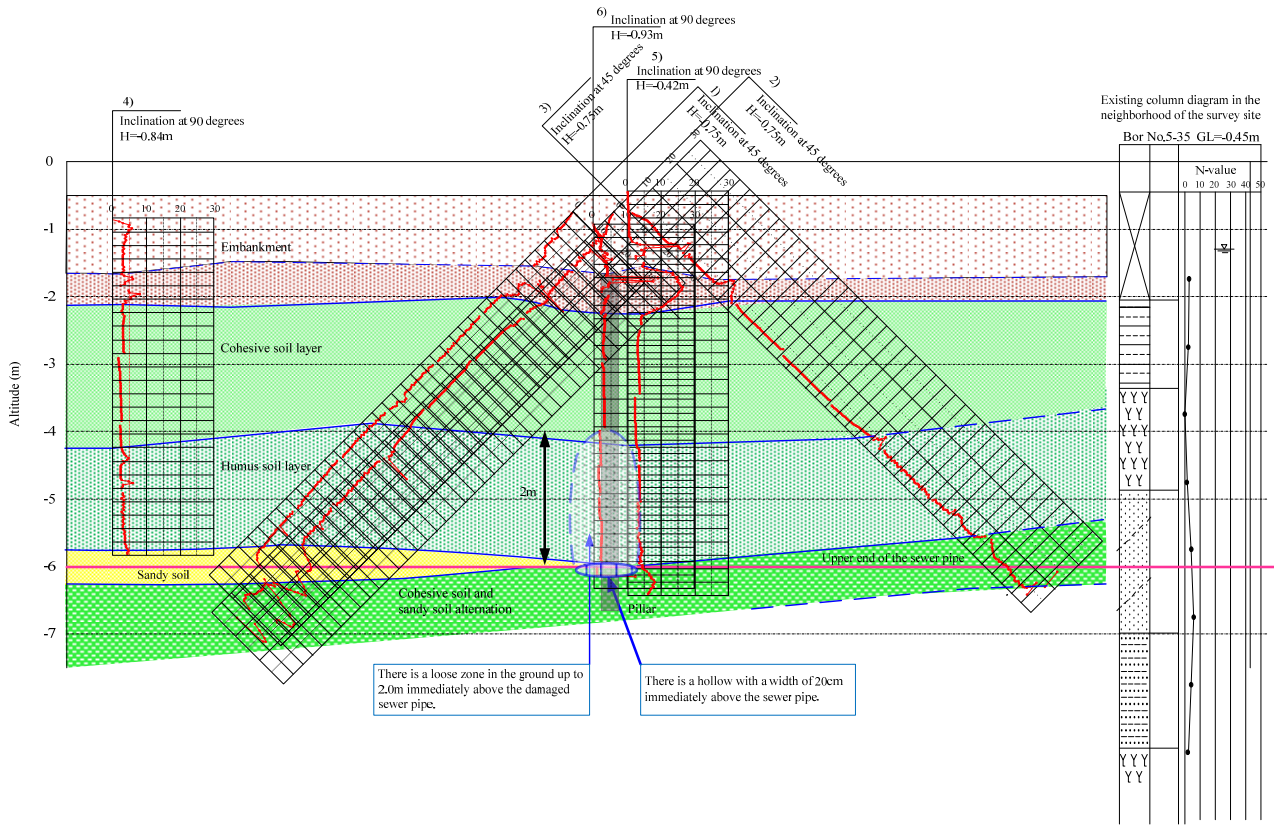

Figure 15. NSWS testing result and geological longitudinal diagram (projecting onto the center line of a sewer pipe)

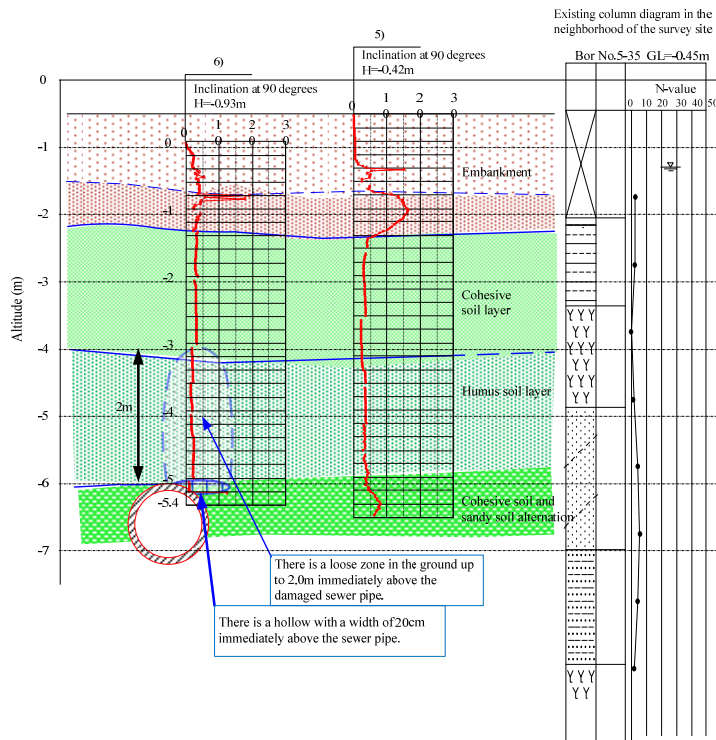

Figure 16. NSWS testing result and geological latitudinal diagram

with a load range of 0 to 1000N.

The NSWs test machine will hereafter be established as a new ground measuring tool by using its various features. It is expected to be applicable in various situations like behavioral changes in the soil such as loosening etc. due to collapse or fall, surveying of boundary specification and extension, and studying various soils ranging from super soft zones to boulder soil.
